Abstract

Background: The slow Wallerian Degeneration (*Wld^S*) gene specifically protects axonal and synaptic compartments of neurons from a wide variety of degeneration-inducing stimuli, including; traumatic injury, Parkinson's disease, demyelinating neuropathies, some forms of motor neuron disease and global cerebral ischemia. The *Wld^S* gene encodes a novel Ube4b-Nmnat1 chimeric protein (*Wld^S* protein) that is responsible for conferring the neuroprotective phenotype. How the chimeric *Wld^S* protein confers neuroprotection remains controversial, but several studies have shown that expression in neurons *in vivo* and *in vitro* modifies key cellular pathways, including; NAD biosynthesis, ubiquitination, the mitochondrial proteome, cell cycle status and cell stress. Whether similar changes are induced in non-neuronal tissue and organs at a basal level *in vivo* remains to be determined. This may be of particular importance for the development and application of neuroprotective therapeutic strategies based around *Wld^S*-mediated pathways designed for use in human patients.

Results: We have undertaken a detailed analysis of non-neuronal *Wld^S* expression in *Wld^S* mice, alongside gravimetric and histological analyses, to examine the influence of *Wld^S* expression in non-neuronal tissues. We show that expression of *Wld^S* RNA and protein are not restricted to neuronal tissue, but that the relative RNA and protein expression levels rarely correlate in these non-neuronal tissues. We show that *Wld^S* mice have normal body weight and growth characteristics as well as gravimetrically and histologically normal organs, regardless of *Wld^S* protein levels. Finally, we demonstrate that previously reported *Wld^S*-induced changes in cell cycle and cell stress status are neuronal-specific, not recapitulated in non-neuronal tissues at a basal level.

Conclusions: We conclude that expression of *Wld^S* protein has no adverse effects on non-neuronal tissue at a basal level *in vivo*, supporting the possibility of its safe use in future therapeutic strategies targeting axonal and/or synaptic compartments in patients with neurodegenerative disease. Future experiments determining whether *Wld^S* protein can modify responses to injury in non-neuronal tissue are now required.

Background

Degeneration of axonal and/or synaptic compartments of neurons is an early and pathologically important process in many disorders of the human nervous system, ranging from Alzheimer's disease and Batten disease through to multiple sclerosis and motor neuron disease [1-8]. Therapies designed to specifically delay or halt the progression of axonal and synaptic degeneration are therefore actively being sought for a wide range of neurological disorders.

The most robust delay in axonal and synaptic degeneration reported to date in animal models of neurological disorders has been generated by the introduction of the slow Wallerian degeneration (*Wld^S*) gene. To date, the *Wld^S* gene has been shown to significantly modify disease onset and/or progression in animal models of traumatic axonal injury [9,10], Parkinson's disease [11,12], demyelinating neuropathies [13], some forms of motor neuron disease [14] and cerebral ischemia [15]. These experiments highlight the potential for using the *Wld^S* protein and/or its downstream molecular interactions to generate novel therapeutic approaches for the treatment of neurological disorders. Importantly, the ability to successfully deliver the *Wld^S* gene and confer robust neuroprotection using gene therapy approaches [16,17] has opened up the possibility of directly delivering *Wld^S*-related therapies to human patients.

The chimeric *Wld^S* gene occurred as the result of a spontaneous mutation in the C57BL/6 line of mice (originally termed C57BL/6/Ola [9]), resulting in a tandem triplication of a region already present on the distal region of chromosome 4. Mice carrying the *Wld^S* mutation are otherwise indistinguishable from their C57BL/6J strain mates in genotyping of more than 50 microsatellite markers and restriction fragment length polymorphisms (RFLPs [18-20]). The triplicated region contains sequences coding for *Nmnat1*, *Rbp7* and *Ube4b* [21]. The boundaries within the triplicated region result in 2 copies of a fusion gene comprising the N70 terminal amino acids of *Ube4b* and the entire coding region of *Nmnat1* (C Terminal 285 amino acids), linked by 18 amino acids from the 5' untranslated region of *Nmnat1* which are not normally expressed [18,21,22]. The chimeric portion of the triplication (i.e. the N-70 *Ube4b*/*Nmnat1* C-303 chimera) has been shown to be sufficient to recapitulate the *Wld^S* phenotype through the generation of transgenic lines in mice, rats and *Drosophila* [23-25].

Although the *Wld^S* gene has obvious therapeutic potential, its mechanism of action remains unclear. However, several studies have shown that expression of *Wld^S* protein in neurons *in vivo* and *in vitro* induces changes in core cellular pathways, including: NAD biosynthesis, ubiquitination, the mitochondrial proteome, cell cycle status and

cell stress [17,26-28]. Even though the extent to which each of these modifications contribute to the neuroprotective phenotype remains unclear, the fact that *Wld^S* modifies key cellular pathways raises potential problems for its use as a therapeutic agent that have yet to be investigated. For example, it is conceivable that changes in NAD biosynthesis pathways and/or cell cycle pathways in non-neuronal organs and tissues may alter their form and/or function.

Here, we have undertaken the first detailed study of the effects of *Wld^S* expression in non-neuronal tissues *in vivo*. We show that *Wld^S* protein is expressed at differing levels in a range of non-neuronal organs in *Wld^S* mice. Systemic expression of *Wld^S* did not affect overall body weight or growth. Gravimetric and histological analysis of a wide range of organs and tissues confirmed no changes in *Wld^S* mice. We also demonstrate that previously reported alterations in cell cycle and cell stress proteins reported in *Wld^S* brain tissue are a neuronal-specific response not observed in non-neuronal organs *in vivo*.

Results

Wld^S expression is not limited to neuronal tissue in vivo

Despite numerous reports in the literature concerning the therapeutic potential of the *Wld^S* gene (see background above), no previous studies have undertaken a rigorous assessment of the consequences of *Wld^S* expression in non-neuronal tissue. We first examined the expression of *Wld^S* protein and RNA levels in a variety of organs from *Wld^S* mice and wild-type controls and compared expression levels to those observed in the cerebellum [29,30]. Organs examined included liver, kidney, heart, lung and spleen. We used quantitative fluorescent western blotting techniques to assess and compare protein expression levels using a proven antibody for the *Wld^S* protein (*Wld^S*-18 antibody [23,30,31]; Figure 1). Example bands are shown in Figure 1A for liver (which had little to no *Wld^S* protein expression), spleen (intermediate levels of expression) and the cerebellum (strong expression).

These experiments showed that *Wld^S* protein expression was not limited to neuronal tissue, but that it was not strongly expressed in all organs examined (Figure 1B). For example, the liver had the lowest expression at 0.06 ± 0.09 (mean \pm SEM) fold increase compared to wild-type background signal, the spleen showed a 6.27 ± 1.05 fold increase, whereas the cerebellum showed a 17.82 ± 0.96 fold increase. We also examined RNA expression in *Wld^S* mice (Figure 1C) and found that RNA expression varied greatly between different organs and did not necessarily correlate with protein expression. For example, the liver (which showed the lowest protein expression of the organs examined) had relatively high RNA expression levels, approaching those observed in the cerebellum. Taken

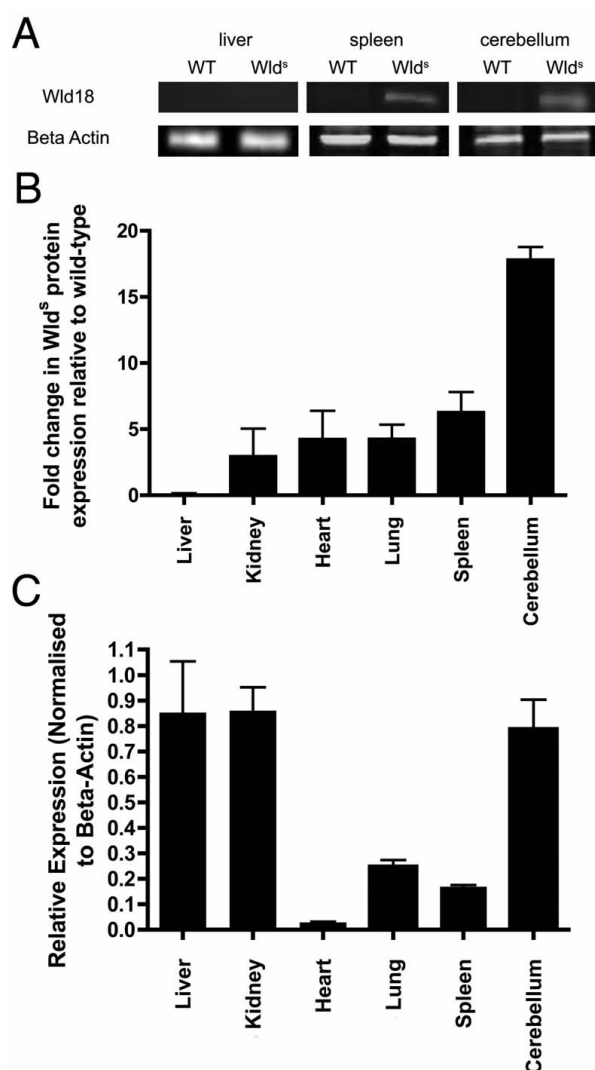

Figure 1
Expression of Wld^S protein and mRNA in non-neuronal tissue. A - Representative examples of bands obtained with quantitative fluorescent western blots from wild-type and Wld^S mouse liver, spleen and cerebellum probed with antibodies against Wld^S protein (Wld-18) and beta-actin (loading control). B - Wld^S protein levels in organs from Wld^S mice expressed as fold change in protein relative to wild-type tissue. Note that all organs except for the liver showed significant levels of Wld^S protein, but none to the same magnitude as found in the cerebellum. C - Wld^S RNA levels in organs from Wld^S mice shown as relative expression normalised to wild-type. Note that RNA levels did not always match protein expression levels (c.f. Panel A). A minimum of 3 mice per genotype were used for all experiments.

together, these findings demonstrate that Wld^S protein and RNA are present in a range of non-neuronal organs at differing levels, but also demonstrate that the presence of RNA does not always indicate that Wld^S protein will also be present at comparable levels.

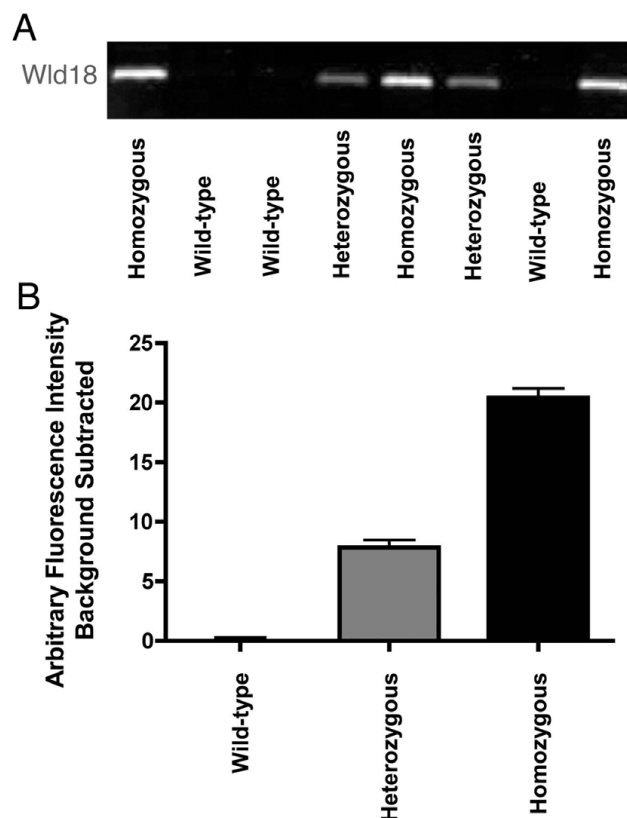

Figure 2
Wld^S mice can be accurately genotyped by quantitative western blots of tail tip protein expression. Tail tips were homogenized in RIPA buffer and following a BCA assay, 30 µg of protein were loaded per lane of a pre-cast gradient gel (see methods section). A - Representative example bands obtained with quantitative fluorescent western blots from a litter of mice produced by a heterozygous breeding pair. The litter contained wild-type, heterozygous and homozygous Wld^S mice. Blots were probed for Wld^S protein levels using the Wld18 antibody. Tubulin was used as a loading control (data not shown). B - Wld^S protein expression shown as arbitrary fluorescence units, illustrating that protein expression was roughly doubled in homozygous mice compared to heterozygous mice. N = 4 wild-type mice, N = 3 heterozygous Wld^S mice and N = 5 homozygous Wld^S mice.

The observation that Wld^S protein is strongly expressed in non-neuronal tissues led us to investigate whether there would be sufficient protein in tail tips to facilitate accurate genotyping of Wld^S mice using western blotting. We found that quantitative western blotting techniques easily distinguished between wild-type, heterozygous and homozygous Wld^S mice (Figure 2).

Systemic expression of Wld^S did not affect gross appearance or growth rates

In order to test whether systemic Wld^S expression affected total body weight, mice were bred from parents hetero-

zygous for the *Wld^S* mutation (see methods). Litters from this heterozygote cross contained mice which were null for *Wld^S* (WT), mice which were heterozygous for *Wld^S* (Het) and mice which were homozygous for *Wld^S* (*Wld^S*). All experimental comparisons were carried out within litters to remove any potential effects of background strain. There were no obvious qualitative differences in the size or behaviour of mice within litters. Figure 3A shows 5 female mice from the same experimental litter (containing a mixture of WT, Het and *Wld^S* mice), indistinguishable from one another. Mice were weighed at regular intervals post weaning up to 2 months of age. There were no significant differences between the body weights of WT, Het and *Wld^S* mice at any time-point examined ($P > 0.2$, ANOVA; Figure 3B; Het data not shown; $N = 7$ WT, $N = 5$ *Wld^S*).

***Wld^S* expression did not affect gravimetrics or histopathology of non-neuronal tissue**

Detailed necropsies were carried out by an experienced rodent pathologist (DGB) on WT, Het and *Wld^S* litterma-

tes to determine if non-neuronal expression of *Wld^S* protein had any effects on tissue gravimetrics (Table 1) or histopathology (Figure 4). Organs examined for gravimetrics included kidneys, liver, spleen, thymus, heart and whole brain. In order to minimize the effects of natural biological variability within litters data were expressed as organ weight per grams/body weight. No significant differences were observed between mice from any of the 3 genotypes (Table 1). Mice were also examined for alterations in body fat deposits (interscapular, pelvic, subcutaneous and mesenteric), with no evident differences (data not shown).

Histopathological assessments were carried out on the following organs and tissues: kidney, heart, lungs, mediastinum, liver, gallbladder, urinary bladder, vagina, uterus, ovary, spleen, pancreas, lymph nodes, salivary gland, pituitary gland, adrenal gland, stomach, intestines (6 levels), calvarial bone, femur, tibia, knee joint, spine and spinal cord (4 levels, transverse sections), eyes, head, various sympathetic and parasympathetic ganglia, brain (transverse sections at 250 μ m intervals). No significant differences were observed between any of the genotypes. Example sections for comparison are shown in Figure 4. Figure 4A shows representative images of liver from wild-type and *Wld^S* mice, a tissue with little to no detectable *Wld^S* protein expression (see Figure 1). Note the presence of normal hepatocyte nuclei, sinusoids and central veins in both images. Figure 4B shows representative images of kidney cortex, a tissue with intermediate levels of *Wld^S* protein expression, showing the presence of normal glomeruli, Bowman's capsules and cortical tubular profiles. Figure 4C shows representative images of spleen, a tissue with high *Wld^S* protein expression, with normal red pulp and white pulp lymphoid accumulations.

Cell cycle and cell stress alterations are specific to neuronal tissue

We have previously reported alterations in proteins involved with cell cycle and cell stress in non-injured neural tissue from *Wld^S* mice *in vivo* and *in vitro* [26,27]. In order to determine whether similar changes were instigated in non-neuronal organs and tissues expressing *Wld^S* protein we examined expression levels of the cell stress marker antiphosphohistone H2Ax (H2Ax) and a marker of cell cycle progression acetylated histone H3 (H3) in liver, kidney, heart, lung, spleen and cerebellum from wild-type and *Wld^S* mice. Example bands for both of these proteins are shown in Figure 5A. As previously demonstrated there was a significant ($P < 0.001$; unpaired t-test) increase in expression of both cell stress and cell cycle markers in *Wld^S* cerebellum compared to wild-type (Figure 5). However, no changes in expression of either of these proteins were found in any of the non-neuronal organs examined (Figure 5). Thus, previously reported dif-

Figure 3
Systemic expression of *Wld^S* does not affect gross appearance or growth rates of mice. A - Photograph of 2 month old female mice from a representative litter produced by heterozygous *Wld^S* breeding pairs. This litter contains wild-type, heterozygous and homozygous *Wld^S* mice. There was no obvious gross difference in size, appearance or behaviour. B - Line graph showing body weight plotted against mouse age in days for wild-type (grey line) and *Wld^S* (black line) mice. No significant differences were observed between genotypes at any time-point examined (Anova). $N = 7$ wild-type, $N = 5$ *Wld^S*.

Table 1: *Wld^S* protein expression did not affect gravimetrics of non-neuronal organs (bwt: body-weight)

	WT Mean	WT SEM	Wld ^S Mean	Wld ^S SEM	t test
Bwt (g)	25.46	1.39	23.56	1.61	ns
Kidneys (g/bwt)	14.20	2.23	17.37	0.62	ns
Liver (g/bwt)	62.16	1.66	57.06	2.51	ns
Spleen (g/bwt)	3.73	0.25	4.24	0.44	ns
Thymus (g/bwt)	3.03	0.34	3.66	0.35	ns
Heart (g/bwt)	6.59	0.33	6.63	0.32	ns
Brain (g/bwt)	20.65	1.36	21.08	0.86	ns

ferences in cell cycle and cell stress status appear to be a neuronal-specific response to expression of *Wld^S* at a basal level.

Discussion

Here we have shown that *Wld^S* RNA and protein are expressed at differing levels in a range of non-neuronal organs in *Wld^S* mice but did not influence overall body weight or growth. Gravimetric and histological analysis of

a wide range of organs demonstrated that the presence of *Wld^S* RNA and/or protein had no overt influence on non-neuronal tissues at a basal level. We have also shown that previously reported alterations in cell cycle and cell stress proteins reported in *Wld^S* brain tissue are neuronal-specific and are not observed in non-neuronal organs *in vivo*. It will now be of interest to establish whether *Wld^S* protein can modify responses to injury in non-neuronal tissues and organs, where it is expressed. Expression data in the current study show that the spleen has a comparatively high level of protein, suggesting that this organ may be useful for such studies.

These data demonstrate that downstream consequences of *Wld^S* expression, incorporating pathways including NAD biosynthesis, ubiquitination, the mitochondrial proteome, cell cycle status and cell stress [17,26-28], do not have any major adverse effects on non-neuronal organs. This suggests that the utilization of *Wld^S*-based therapeutics for treating neurodegenerative conditions can be considered safe for other body systems, should the treatment spread beyond the confines of the nervous system (e.g. unintentionally or as a result of systemic administration). Studies reporting that *Wld^S*-mediated neuroprotection (as well as many of its downstream effectors such as Nmnat pathways) can be successfully delivered to the nervous system using approaches such as viral gene delivery suggest that *Wld^S*-based therapeutics are a realistic possibility [16,17].

Our experimental data have also revealed nervous system-specific effects of *Wld^S* expression. The finding that modifications in cell cycle and cell stress status previously reported in neurons expressing *Wld^S* [27] are not replicated in non-neuronal tissues suggests that neurons may have distinct intrinsic responses to the presence of *Wld^S*. One possible explanation for this is that neurons are terminally differentiated cells whose cell cycle status is markedly different from many non-neuronal cells (for review see [32]). Whether or not this contributes directly to the neuroprotective phenotype remains to be determined. Nevertheless, these data support the hypothesis that *Wld^S* acts by targeting a specific step(s) in degenerative pathways intrinsic to neurons [33].

Figure 4
***Wld^S* protein expression did not affect histopathology of non-neuronal organs.** H & E staining of tissues showed no obvious qualitative differences between wild type (left), heterozygous (data not shown) or homozygous *Wld^S* mice (right) for liver (A), kidney (B), and spleen (C). The selected organs shown represent non-neuronal organs with low (liver), medium (kidney) and high (spleen) levels of *Wld^S* protein expression. Scale bar = 100 μ m (A&B), 200 μ m (C).

Figure 5
Cell cycle and cell stress pathway alterations were specific to neuronal tissue. A - Representative examples of bands obtained from quantitative fluorescent western blots from wild-type and *Wld^S* mouse spleen and cerebellum probed with antibodies against cell stress (H2Ax) and cell cycle (H3) proteins (beta actin is shown as a loading control). Spleen was chosen because it had the highest *Wld^S* protein expression levels of all the non-neuronal tissues examined (Figure 1). Note the increases in H2Ax and H3 in *Wld^S* cerebellum compared to wild-type mice, but no change in the expression of either protein in the spleen. B - Bar chart showing cell cycle (H3) and cell stress (H2Ax) protein levels in a range of organs from *Wld^S* mice expressed as fold change in protein relative to wild-type. Both proteins examined showed only very minor fluctuations in expression levels in non-neuronal tissue (left hand side of dotted line). The magnitude of change in non-neuronal tissue did not begin to approach those observed in the cerebellum of *Wld^S* mice (right hand side of dotted line). A minimum of 3 mice per genotype were used for each experiment.

Conclusions

We conclude that expression of *Wld^S* protein has no adverse effects on non-neuronal tissue at a basal level *in vivo*, supporting the possibility of its safe use in future therapeutic strategies targeting axonal and/or synaptic compartments in patients with neurodegenerative disease.

Methods

Mouse breeding

Natural mutant C57Bl6/*Wld^S* (*Wld^S*) mice and C57Bl/6 (wild-type) mice were obtained from Harlan Olac Laboratories (Bicester, UK) and housed within the animal care facilities in Edinburgh. All animal experiments were carried out in accordance with the guidance and rules of, and under license from, the UK Home Office. Breeding pairs made up of one *Wld^S* mouse and one wild-type mouse were used to generate heterozygous *Wld^S* mice. These mice were then bred to produce litters which contained mice null for the *Wld^S* mutation (wild-type), mice heterozygous for the mutation (Het) and mice homozygous for the mutation (*Wld^S*). All data were obtained from tissue harvested from 1-2 month old mice. For body weight measurements, mice were weighed every 2 days post weaning. A minimum of 3 mice were used per group for all experiments.

Genotyping

Mice were bred as detailed above, ear-notched and assigned individual identifying numbers which were used so the experimenter remained blind to the genotype of individual mice throughout. Mice were genotyped post mortem and their genetic status was only assigned after data collection and analysis was complete. Mice were initially genotyped by quantitative western blotting for *Wld^S* protein expression levels using protein extracted from tail tips using similar methodology described below (see Figure 2). These genotypes were all validated by real-time PCR as previously described [34].

Necropsy

Mice were killed with carbon dioxide gas and immediately weighed. Selected organs were weighed and a standard panel of organs were immersion-fixed in 10% neutral-buffered formalin for histopathology. Fixed organs were embedded in paraffin, sectioned at 4 mm, and stained with hematoxylin and eosin. All analyses were undertaken with the investigator blind to the genotype of each animal.

RNA extraction & qRT-PCR

Cerebellum, liver, spleen, thymus, lung, and heart from 6-week-old female *Wld^S* mice were flash frozen on dry ice and mRNA was extracted using the RNAEasy Kit (Qiagen, Valencia, CA). Messenger RNA from all tissues was transformed into cDNA using the Superscript III kit (Invitrogen, Carlsbad, CA). Quantitative real-time PCR (qRT-PCR) was performed to examine *Wld^S* gene expression using a Sybr-Green '1-step qRT-PCR kit' (Invitrogen) on an ABI PRISM 7700 Instrument (Applied Biosystems, Foster City, CA). The following primer sequences were used:

Wld^S-726F TGTGCCCAAGGTGAAATTGC

Wld^S-818R ACGATTTCGCTGATGTCCTCC

β -actin was used as a control gene. To verify that there was minimal genomic DNA contamination, we also performed qRT-PCR analysis of selected extracted mRNA samples prior to conversion to cDNA, which demonstrated a negligible genomic DNA presence (10,000× less).

Protein extraction & quantitative western blotting

Mice were killed by cervical dislocation and organs for examination rapidly removed. Protein was extracted from tail tips, cerebella and organs including the kidney, liver, heart, lung and spleen of age- and sex-matched mice in RIPA buffer with 10% protease inhibitor cocktail (Sigma) as previously described [26,27]. 30 µg of protein per lane was separated by SDS/Polyacrylamide gel electrophoresis on 4-20% pre-cast NuPage 4-12% Bis Tris gradient gels (Invitrogen) and then transferred to PVDF membrane overnight. The membranes were then blocked using Odyssey blocking buffer (Li-COR) and incubated with primary antibodies as per manufacturers instructions (anti acetyl Histone H3 - Lake Placid Biologicals; antiphosphohistone H2Ax - Upstate; anti beta actin and anti beta-III-tubulin - Abcam). Wld-18 antibodies were a kind gift from Dr Michael Coleman and were used as previously described [30]. Odyssey secondary antibodies were added according to manufacturers instructions (Goat anti rabbit IRDye 680 and Goat anti mouse IRDye 800). Blots were imaged using an Odyssey Infrared Imaging System (Li-COR Biosciences). Scan resolution of the instrument ranges from 21-339 µm and in this study blots were imaged at 169 µm. Quantification was performed on single channels with the Li-COR analysis software provided, as previously described [26,27].

Authors' contributions

TMW participated in the design of the study, carried out experiments, analysed data and drafted the manuscript. DGB carried out necropsy experiments and analysed data. DT carried out experiments. AMT/KMB/JWT carried out QPCR experiments. THG conceived of the study, participated in its design and coordination, analysed data and drafted the manuscript. All authors read and approved the final manuscript.

Publish with **BioMed Central** and every scientist can read your work free of charge

"BioMed Central will be the most significant development for disseminating the results of biomedical research in our lifetime."

Sir Paul Nurse, Cancer Research UK

Your research papers will be:

- available free of charge to the entire biomedical community
- peer reviewed and published immediately upon acceptance
- cited in PubMed and archived on PubMed Central
- yours — you keep the copyright

Submit your manuscript here:
http://www.biomedcentral.com/info/publishing_adv.asp
